計畫名稱：利用 W 波相逆推震源參數與單位海嘯建立南中國海海嘯預警系統

計畫主持人：中央大學地球科學系 陳伯飛 副教授

1. Introduction

Historically, the tsunami hazards in Taiwan occurred in the North and SW coasts (Soloviev and Go 1974). Those at SW Taiwan are believed to be triggered by earthquakes in the Manila subduction zone and amplified by the steep slope of the South China Sea (SCS) shelf and those in the north are most likely associated with tsunamigenic earthquakes in the Ryukyu subduction zone. In previous project, we have established a tsunami warning system for South China Sea using unit tsunami methods and *W* phase inversion. The purpose of this project is applying the same methodologies to build a tsunami warning system for earthquakes in the Ryukyu subduction zone. Firstly, we introduced methods of unit tsunami and *W* phase inversion. Secondly, we divided the potential source region of the Ryukyu subduction zone into group of unit sources and calculate the propagation of each unit source as unit tsunamis stored in database. Thirdly, we sorted out past large earthquakes in the Ryukyu subduction zone and collected data from Broadband Array in Taiwan for Seismology (BATS; Kao et al., 1998) and F-NET to assess the results of *W* phase inversion. Finally, we conclude this study.

2. Methods and Results

2.1. Building Database of Unit Tsunamis

The potential source region of the Ryukyu subduction zone was divided into 107 square pixels, each with 1.0° ×1.0° in size and an initial vertical seafloor displacement of 1 m was assigned to each pixel to constitute the group of unit sources (Figure 1). We employed Cornell Multigrid Coupled Tsunami Model (COMCOT) to simulate the propagations of each unit source. COMCOT is a finite difference scheme and in our case, we solved for linear shallow water wave equations in spherical coordinates with 1 minute (~1.8 km) and 1 sec in space and time, respectively. The boundary conditions are total reflection for ocean-land interfaces and radiation for map boundaries. We set up 32 virtual stations representing existing tidal stations of Central Weather Bureau (Figure 2). The wave field of one station from one unit source is referred to the unit tsunami corresponding to the station-unit source pair. For each unit source, we simulated for four-hour propagations (Figure 3) with the

resulting wave fields as a function of time at the 32 stations stored in database (Figure 4). In the end, a total of 107×32 unit tsunamis were stored in database for synthetics of tsunami waves in real events. The stored unit tsunamis are readily available for arrival time predictions even without the occurrence of real events. We applied Short Time Average over Long Time average (STA/LTA; Allen 1982), a conventional scheme for picking seismic P and S phases, to automatically pick the arrival times of unit tsunamis (Figure 5) with results shown as arrival time map (Figure 6) and stored in database for arrival time predictions.

2.2 *W* Phase Inversion

We refer readers to Kanamori and Rivera (2008) regarding theory, modeling, and source inversion of *W* phase. We recapitulate here that *W* phase can be interpreted as superposition of the fundamental mode, first, second and third overtones of spheroidal modes at long period and can be synthesized by normal-node summation. The Green's functions of six moment tensor elements are pre-computed for a distance range of $0° \leqq \Delta \leqq 90°$ with an interval of 0.1° and for a depth range of 0-760 km. The synthetic waveforms of an earthquake are derived by convolving the Green's function with its moment rate function, which is a triangular function defined by two parameters, half duration, t_h, and the centroid delay, t_d (Figure 7). The broadband seismic data are deconvolved to displacement with instrument response removed and a band-pass filtered. A time period of 15Δs (Δ epicentral distance in degree) from the beginning of *P* wave is windowed to extract W phase. A time domain recursive method is used not only for real time operation but also for using available data to the point where it gets clipped at the large amplitude *S* or surface waves. The same procedures are applied on synthetic waveform and, together with data, a linear inversion is performed on concatenated time series using a given hypocenter location and origin time.

We sorted out earthquakes between Jan. 2000 and July 2011 with moment greater than 10^{25} dyn-cm and bounded by (10°N, 26°N) and (115°E, 135°E) from the GCMT catalogue (Dziewonski et al., 1981; Ekström et al., 2005). Figure 8 shows the distribution of earthquakes. A visual regional array, including the bulk of current BATS and selected stations from F-NET is set up to conduct *W* phase inversion (Figure 8). The LH channel data (1 smaple-per-second) of earthquakes from the array are collected through Web site for source inversion of *W* phase and the results are compared to GCMT solutions of the same event. Some stations are eliminated with their data continually exhibit low quality (e.g., LYUB). We tested for six scenarios divided into two groups: using vertical component only and using all three ZNE components. In each group, three sets are tried with different level of knowledge on

earthquake parameters: (1) using the GCMT centroid parameters (not practical in real case), (2) using the hypocenter parameters (lon., lat., depth, origin time) reported by the PDE (Preliminary Determination of Epicenters) catalogue, and a centroid time, t_d, determined by grid search; the source half duration, t_h, is set equal to t_d, (3) the same as (2) except the centroid location (lon., lat.) determined by a 2-dimensional grid search (depth fixed at PDE's). We present the results with gCMT location, t_d location, and (t_d+xy) location, respectively. The cutting distance – within which data are removed – is determined to be 1.0°. The inversion is iterated three times with a higher threshold is assigned on each to keep data for inversion. An example of fitting between synthetic and observed waveforms of vertical component for the 20090805 event is shown (Figure 9). The frequency band used to filter seismic waveforms basically follows Table 1 of Hayes et al. (2009).

We present the comparisons of M_w (GCMT) and M_w (W phase) for each of six scenarios in Figure 10, with the mean values of absolute magnitude differences and their standard deviation shown. We note that the results ZNE components are significantly better than their counterparts of *Z* component only. Column-wise, solutions of gCMT location exhibit least mean values of magnitude differences regardless vertical components only (left column) or ZNE three components (right column). However, the GCMT parameters are not available in real time application. Among the remaining four scenarios, the one with least value of magnitude difference is results of t_d location with three components (right column, middle). The larger events (M_w > 6.6) also tend to exhibit more consistent results with those of GCMT solutions. This implies that using PDE hypocenter and grid searching for t_d on ZNE three component data can serve as routine operational procedures for *W* phase inversion of SCS earthquakes.

3. Conclusions

In this study, following previously proposed combining *W* phase inversion and unit tsunami methods, we build a tsunami warning system in Taiwan for earthquakes in the Ryukyu subduction zone. The *W* phase inversion allows us to rapidly determine moment tensors of large earthquakes for the calculations of vertical seafloor displacements (Okada, 1985). The applicability of *W* phase inversion for Ryukyu subduction zone earthquakes using BATS stations and some of F-net stations has been tested and the best scenario determined to be t_d location with three components. We have built a database of unit tsunamis for the source region of the Ryuku subduction zone and the prediction of arrival times is readily available once the epicenter of tsunamigenic earthquake is known.
